Lord of the Lemons: Origins and Dynamics of State Capacity

THILO R. HUNING† and FABIAN WAHL‡

Abstract
To better understand the role of taxation in the emergence of states, this article presents an incomplete contract model of an agricultural society in which information asymmetries cause inefficient taxation, and hence outmigration, uprisings, and rent-seeking, but also urbanization. We propose a geographic index of information costs, observability, to test our model. Our case study is the Holy Roman Empire, which had a relatively homogeneous institutional framework, state of technology, culture, and ethnic composition across hundreds of observed states, for over 500 years. We find a robust link between observability and states’ tax capacity, their size, and their survival.

For modern examples and literature review, see Olsson and Hansson (2011). For historical overviews, see Dincecco and Prado (2012), Johnson and Koyama (2017) and (Dincecco).
there is consensus that some level of state capacity is essential to ensure basic public good provision (Acemoglu, 2005). There is debate about what allowed some states to establish this capacity while others failed. Long-run studies point at the self-reinforcing nature of state capacity\(^2\) and have identified important structural changes around and after 1500, from the ‘military revolution’ to the Industrial Revolution until the emergence of the welfare state\(^3\), all of which radically changed the rules of development. When searching for the optimal point in history to study the development of state finances, one has to study the period from just before until just after these structural changes, in order to avoid going back too far in time\(^4\). In this paper, we will trace hundreds of uniquely homogeneous states that were arranged in a federation, the Holy Roman Empire (HRE), through these radical changes, 1250–1789. We find evidence for a mechanism that links observability of (taxable) agricultural output to state capacity. This mechanism explains differences in state development during the medieval period, but not afterwards.

Our argument is based on the idea that states emerged when there was agricultural output that needed to be protected (see Bates et al. (2002); North et al. (2009) and more recently Dal Bó et al. (2015); Boix (2015); Mayshar et al. (2015)). Some believe states emerged from tribal societies realizing that security could be provided more efficiently in a central way (Bean, 1973). Tribal societies therefore set-up a voluntary ‘social contract’ (Rousseau, Hobbes) between the group and a ‘violence specialist’ (North et al. 2009, p. 20) who was granted the ‘monopoly of violence’ (Weber, 1919). Others do not believe in a voluntary contract, but in states emerging from coercion by a ‘stationary bandit’ (Olson, 1993) stealing from his subjects.\(^5\)

\(^2\)Examples include Allen (2009); Findlay and O’Rourke (2009); Mokyr (2011); Dincecco (2015); Karaman and Pamuk (2013); Ang (2015).

\(^3\)These revolutions include the military revolution (Tilly, 1993; Diamond, 1999; Simms, 2015; Gennaioli and Voth, 2015; Boix, 2015); urban revolution (Allen, 2009; Bosker et al., 2013; Voigtlander and Voth, 2013; Karaman and Pamuk, 2013; Boix, 2015); Abramson (2017), the discovery of the Americas (Hoffman, 2011; Nunn and Qian, 2011; Simms, 2013; Hoffman, 2015); the printing press (Rubin, 2014; Dittmar and Seabold, 2015); the Reformation (Cantoni, 2012; Cantini et al., 2016; Dittmar and Meisenzabel, 2017); the Enlightenment (Mokyr, 2011); the Financial Revolution (Neal, 2015); the French Revolution and its consequences (Acemoglu et al., 2011; Boix, 2015); nationalism (Anderson, 1983); and the expansion of public good provision in general (Alesina and Spolaore, 1997; Bolton and Roland, 1997; Alesina et al., 1999; Goldin and Katz, 2009).

\(^4\)The few studies concerned with the determinants of state capacity prior to 1500 AD are primarily those examining, in the spirit of Diamond (1999), the impact of the different timing of the Neolithic revolution across the world on the development of statehood (Borcan et al., 2016; Ang, 2015) or those focusing on differences in transparency of agricultural output and the role of environmental circumscription in ancient states (Mayshar et al., 2017; Schönholzer, 2017). Fenske (2014) analyses the role of different gains from trade due to differences in ecological diversity for state capacity in pre-colonial Africa. Exceptions to this are Abramson (2017) and Ko et al. (2016). These papers analyze the determinants of political centralization and state formation for very early periods or over a very long time (e.g. from the Middle Ages until today) and, in this, are closely related to our paper in this.

\(^5\)This view of an involuntary agreement is shared by figures as prominent as Marx and Engels, but also Tilly (1985). See Fukuyama (2011, Ch. 21) for an overview. An addition to this argument is the circumscription theory by Carneiro.
What both sides agree on is that this ‘contract’, either voluntary or involuntary, exchanges violence (protective or coercive) in return for taxation. Many authors have therefore stressed the role of the former and view military technology as decisive for state development (see Tilly, 1993; Diamond, 1999; North et al., 2009; Gennaioli and Voth, 2015; Boix, 2015; Ko et al., 2016). Museums and arsenals of historic tools, weaponry, and war records from most of human history have guided the understanding of the role of the horse, the chariot, the canon, or general conscription for political order. The other side of the contract, efficient taxation, is less prominent, but understanding it is decisive for modern development economists. At its core aspect is the quality of information about taxable output. The weaker the information, the more our bandit would find himself between Scylla and Charybdis. Demanding an excess of taxes, he bites the hand that feeds him. Demanding too little, less modest rivaling bandits will take his place. Free-riding and false accusation of free-riding also threatens also the consent of those governed by a voluntary contract. Both the voluntary and the involuntary contract suffer from the problem of asymmetric information between the source of the taxes and the provider of ‘security’. From the perspective of a peasant who is overtaxed due to false information, the distinction between these two origins of a state is, therefore, of purely theoretical nature.

In addition, overtaxation will lead rational agents to hide some parts of the harvest (and spend effort trying to avoid being caught), just to prevent starvation. States can try to reduce information asymmetries by creating a political order, a hierarchy, to collect data on agricultural output. This introduces multiple principal-agent problems and the problem of rent-seeking (Krueger, 1974; Olson, 2008; Acemoglu and Robinson, 2012). Therefore, imperfect information about taxable agricultural output translates to high information costs, undermines political institutions, may lead to conflict within a state, reduces state capacity, and in the end limits the states development in general—and precisely because of the information asymmetry, this is true even with the most benevolent ruler. Unlike winners of wars, rent-seeking tax collectors, lords, and officials did not boast about their successes. Their relics seldom survived in a form to anything that could be excavated today and analyzed in a structured fashion today. However, state capacity in an early agricultural society has to be viewed as an equilibrium solution between military technology and (1970). Carneiro noted that early states emerged predominantly in areas surrounded by infertile areas (such as deserts), and assumed this provided a natural barrier against fleeing from violent rulers.
To formalize this argument, we develop a macroeconomic model that links state capacity to geographic circumstances, namely a combination of the quality, and observability of agricultural output. This model is inspired by the study of Mayshar et al. (2017), who develop a principal–agent model of an agricultural state, in which state rulers maximize state revenue under information asymmetry about agricultural output, which is geographically determined. If output is perfectly predictable, rulers can extract full effort from their subjects. In a state with a high spatial variation of soil quality, for example, the actual quality of a single plot is hard to observe, meaning the ruler will have to estimate the endowment. The lower the observability of soil quality, the lower the state capacity. The more heterogeneous, and thus less observable the productive potential of each plot, the higher the costs of observation. Our theoretical model extends the work of Mayshar et al. (2017) several respects. Their model is not empirically testable as they only distinguish between two types of soils, those with low and those with high observability and provide only two case studies from ancient times. We generalize their micro-level principal-agent model to a macro-level two-sector output model with a continuous observability measure. We also extend their model to explain the failure and survival of feudal states and the changing importance of agricultural and economic determinants of state capacity over time. Urbanization is now modeled as part of rulers’ optimization problem.

To test our theoretical propositions empirically, we compute a variable that proxies the observability of agricultural output (and thus the information costs in an agricultural society). This measure is based on spatial variation of the crop suitability within a region. Output is measured using the average caloric yield that can be obtained from harvesting crops. We base our measure of observability on the caloric suitability index developed by Galor and Özak (2014, 2015). This index denotes the amount of calories that can be produced in a given area, averaging over the individual caloric yields obtained from planting all suitable crops. This index covers the periods before and after the Columbian exchange. Based on this index we calculate our observability measure as a ruggedness index of caloric yields, i.e. we measure the variation in agricultural output as the…

Our reasoning is also based on the fact that medieval rulers, for example Charlemagne, were not only interested in increasing agricultural output, but also in increasing its observability, uniformity and comparability (Henning, 1994; Hermann, 1985)
variance between the caloric suitability of each cell and that of its neighboring fields. Thus, we capture to what extent the agricultural output of a grid cell diverges from perfect observability (all cells within a grid have the same caloric yield).

We link this observability measure to the states in the HRE at six points in time (1250, 1378, 1556, 1648 and 1789), which are all decisive moments in Central European history (see p. iii of the Appendix). This allows us to abstract from the role of military technology, as this is common across our sample and has been studied extensively. We obtain information and states and their size by digitizing historical maps of the HRE (without the Italian parts) by Wolf (1877). After digitizing these maps, we validated and, if necessary, corrected them using literature on the history of territorial states in the HRE, such as Köbler (1988) and Sante (1964). We also collected reasons for the failure of states.

Using this unbalanced, state-level panel data set, we first show a robust and both economically and statistically significant positive relationship between observability of agricultural output and taxation. We proxy the taxation by the tributes towards the Empire, the ‘Reichsmatrikel’. We then investigate how differences in observability are related to the failure or survival of agricultural states. The results suggest that states with low observability are more likely to disappear because of bankruptcy or war and that observability is positively linked to the probability of state surviving in the Middle Ages. In the following, we find observability being positively related to state size when pooling over all states and periods. The relationship also holds when estimating separate cross sections for each of the six years and when considering the characteristics of neighboring states. It is also robust to controls for many alternative determinants of state capacity, such as access to trade routes and rivers; the availability of important natural resources such as iron, gold or salt; trade fairs; imperial cities; terrain features such as ruggedness and elevation, temperature, suitability for ploughing; the type of the state (i.e. kingdom, duchy, princedom, county, city etc.); the number of battles per state area; and the effect of differences in the appropriability of crops. Results pass various tests of robustness. We use the settled area of a state as dependent variable (the area that is not forested or marshland or the like). We take levels of agricultural observability and state area instead of natural logarithms. We employ an alternative version of the agricultural observability index (based on the assumption that only the crop with the highest caloric yield is
planted), and another version of the index. The cross-sectional estimates, and alternative OLS regressions in which the agricultural observability index is interacted with period dummies, are in line with our theoretical reasoning and historical evidence. Agricultural observability looses its significance as a determinant of state capacity in the early modern period, more specifically in the 16th century. As outlined earlier, this is the timing we would expect. In this point in time, structural changes made the scale effect the dominant factors in predicting state capacity.

Below we provide an overview of relevant historical features, such as the political and societal structure of the HRE. We continue by developing the theoretical model that connects the principal-agent problem to state capacity and size. We introduce the data and outline our empirical strategy to test the theoretical model. This includes a discussion of alternative influences on pre-modern state capacity, and also how we address them. We will discuss the empirical results, and then conclude.

I. State Size in an Agricultural Society

Figure 1: Stylized equilibrium area ($A^*$) of a state in equilibrium between decreasing marginal costs of warfare, $MW$, and increasing, geographically induced and non-linear marginal cost of taxation $MT$, before and after the military revolution that shifts military costs to $MW'$ starting around 1500

We define a state as a geographical unit that competes with fellow states over both territory and labor supply to generate taxes. We are therefore interested in the tax capacity of such a state, and its influence on geographic size and survival. Our model state is predominantly agricultural, as this was by far the leading occupation throughout human history (see Allen 2000 for estimates). We assume that land rents are Ricardian, and that a state’s tax revenue is a function of the available land area and labor force. The general idea that the geographic size of a state is at equilibrium between increasing returns to scale in providing public goods and increasing
obstacles to this provision is well established (see Spolaore, 2014 for a recent overview). Consider Figure 1. Following Bean (1973), we view defense of the territory as the predominant public good, which is provided at decreasing costs per unit of land. During the High Middle Ages changes in technology amplified these decreasing returns to scale, in the ‘Military Revolution’ (Tilly, 1993; Gennaioli and Voth, 2015; Boix, 2015).

Already Adam Smith was concerned with obstacles to state size and capacity, and proposed a mix between geographic variables and administrative constraints

"In countries, such as Italy and Switzerland, in which, on account either of their distance from the principal seat of government, of the natural strength of the country itself, or of some other reason, the sovereign came to lose the whole of his authority. [...] This is the short history of the republic of Berne as well as of several other cities in Switzerland. If you except Venice, for of that city the history is somewhat different, it is the history of all the considerable Italian republics, of which so great a number arose and perished between the end of the twelfth and the beginning of the sixteenth century."

Concerning distance, Olsson and Hansson (2011) have recently shown that across modern countries there is a robust negative relationship between country size and rule of law. In theory, there can be three reasons for their finding. First, the complexity of the process upon which that information is collected (unrelated to distance). Second, the transfer of the information through the organizational structure of the state (weakly related to distance, depending on circumstances). Third, the loss of information due to the physical transport of the information, which we positively rule out for modern times given communication technology.

Regarding the first, more complex processes are harder to understand. Mayshar et al. (2017) show this with Egyptian agriculture, a fairly simple process. The Nile carried with it fertile soil and distributed it evenly across its banks. This means that a primitive tool, the Nilometer was a reasonable indicator for harvest outcomes, in the form of a univariate relationship. By contrast, agricultural output in Mesopotamia depends on multiple variables, as irrigation was more complex.
The process of agriculture in Western and Central Europe was even more complex, and not well understood in the Middle Ages. There are some homogeneous landscapes, where properties of the soil are very uniform, the terrain is even, the wind blows all seeds in the same direction, etc., and other landscapes, where none of this is true. Taxation of output from these landscapes will naturally be based on estimates, and these can vary in their quality. Lacking an objective tool (like the Nilometer), these estimates relied on self-reporting (van Schaik, 1993; Vogeler, 2005). We will outline how different levels of variation, which are geographically determined, yield different qualities of information, and induce information costs.

Information about agricultural output is necessary for taxing an agricultural society. Meteorology, the science of measuring and predicting weather and climate, was rediscovered during the Renaissance. Behringer (1999) goes as far as viewing the emergence of meterology to predict agricultural output as a counter-reaction to witch-hunting—the prevailing practice for overcoming harvest failures during 1300–1600. We can assume that the state of meteorology was so weak, and that investment into the understanding of factors that determine the harvest was so costly, that tax collection depended on adaptive expectations, and also local gentry and officials who were familiar with subjects and landscape. This explains hierarchies, such as the Chinese bureaucracy, the Mamluks in the Middle East, and also the feudal system in Western and Central Europe.

Relying on local knowledge has downsides. In any such hierarchy there is loss of information, even if the incentives of all participants are aligned. In an analogy to the telephone game, there would be some loss of information, but driven more by the number of hierarchy levels than distance. The levels of hierarchy in the HRE were however not dependent of its size, but mostly due to tradition. This could lead us to reject incentive-aligned tax officials if we observe variation in state capacity despite the same number of levels in the hierarchy. At any level in the hierarchy there is a principal-agent problem, and these problems combined limited the expansion of the

---

11 It is important to note that the feudal system was not built from scratch, but relied on existing tribal hierarchies. The alternative, demonstrated by China, reveals however that these structures could be eroded, if the central power is strong enough. This in turn allows us to measure information costs half a millennium ago, unlike in other areas of the world. One can assume that asymmetric information in a bureaucracy would translate to e.g. corruption, which is hard to observe in a historical context. (see also Mitterauer, 2004; Fukuyama, 2011).

12 Consider playing the telephone game. The quality of information is reduced slowly but continuously over time (as people forget) which would be analogous to the distance in our context. Much faster, and the core of the game, is the sharp drop in information quality between two players when one player has to listen and repeat the information.
In the next section, we will trace these problems through the hierarchy of the HRE and show how we can measure them in aggregate.

II. Taxation in the Medieval Holy Roman Empire

We follow the literature in regarding the medieval Roman Empire as a chain of bilateral contracts (North and Thomas 1971; Volckart 2002), through which security is provided from the top down in exchange for goods and services (see Bean 1973; North et al. 2009; Olson 1993). In Figure 2 we see the ends of the chain of bilateral contracts held by the Emperor and the households. Our element of interest, the territorial states, contracts directly with the Emperor, but only connects to households through intermediaries. We will outline how the rents that gentry and officials gain from inter-mediating between state and household are a loss to the rulers, and how rents arise endogenously from the multi-layer principal-agent problem.

1. Households and the Gentry

The lower end, and the smallest political unit of the HRE was the household (see Wilson 2016, p. 508 and Volckart 2002, p. 33). Volckart (2002) distinguishes between three types of contracts that exchange either services or agricultural goods between the household and the low gentry and officials. The most prominent of these was the feudal contract, in which a lord (lat. vilicus) provides security in exchange for agricultural output and compulsory labor for the feudal lord (corvee). The households had the right to decide the use of the land and the yields of the land (“usus et usus fructus” Volckart 2002 p. 40)), but would never gain property over it. This system, developed by the Carolingians, had its origins in the Late Roman Empire, when formerly free peasants were obliged to fill military granaries, and diffused eastwards into the Germanic areas (Mitterauer 2004 p. 42ff.). The lord maintains certain rights of deposition over the feudal state, but grants the household (its serfs) the right to work on the land and retain a portion of the harvest to feed themselves.

13The idea of non-aligned incentives in a company-like state, which is true both for a feudal society and a command economy, is taken from Harrison (2002).
Neither secular nor ecclesiastical states based their taxation upon tradition, but were flexible about the form and quantity of taxation. North and Thomas (1971) have argued that whether a lord would demand goods or services was a question of transaction costs, and depended on the lord’s ability to market each of the products. We employ this idea in our model, since we identify all forms of taxation with their labor input. Inefficiency in acquiring information about the harvest posed a substantial risk to the lord. Tradition and written contracts certainly did not impose an upper bound for taxation, especially due to a very flexible and hence dynamic element: free provision of peasants’ labor services. Labor services were not well codified (Volckart, 2002, p. 9), and allowed rulers to flexibly adjust the quantity of such services to circumstances. For example, a 1222 source from the Eiffel provides instructions on how to persuade peasants to take over new duties, selling them as old traditions (Epperlein, 2003, p. 76).14

One of the most important threats to tax capacity was outmigration. Depending on the demographic circumstances, but especially following the Black Death, outmigration to another feudal state or a Free or Imperial city made states compete for peasants (Volckart, 1997, 2002), and one element of this competition was costs created by incomplete information.15 Rulers’ ability to restrict this migration depended on features such as state capacity and the size of its territory—as it was easier to escape undetected from a small state than a large one (Blickle 2006, Gerteis, 1997). Thus, some rulers were more

---

14 Large and extensive corvées were not unusual (see e.g., the discussion in Blickle (2006) on the particularly repressive feudal system in the Baltic Sea area).

15 The migration from rural areas to cities is considered among German historians to be an important aspect in the demise of the feudal system. They provide a several detailed accounts about conflicts between rulers and city states about fleeing serfs. One of the most conflicted topics between territorial states and cities states was the so-called urban dwellers (“Pfahlbürger”): people who lived outside the area of the city in villages but were citizens of the city—and hence not part of the feudal system. Emperors forbade this type of citizenship several times during the 14th century but did not succeed in preventing it (Blickle 1998). However, as emphasized by Ogilvie (2007, 2011) urban labor markets in pre modern times were highly regulated by guilds, and they often successfully limited immigration to cities. Thus, migration to a city state might not have been possible for everyone or at all times.
Another threat arising from information asymmetries and information costs was revolt. Peasant revolts were common in the HRE throughout the Middle Ages and increased in frequency and intensity in the early 16th century, culminating in the German Peasants’ War in 1525. Although their overall success (especially in the Peasants’ War) was limited, there are numerous examples of peasant revolts against (perceived) overtaxation, restriction of free movement and inheritance rules that resulted in a compromise between the ruler and the peasants. These gradually improved the situation of the peasants and weakened the feudal system in the long-term.

Incomplete information about agricultural output also explains a common phenomenon during the Middle Ages, tax avoidance. The Sachsenspiegel (around 1230), a rich historical source of medieval life in Saxony, allows us to understand how peasants attempted to cheat their rulers. It explicitly states that the quality of the tithe (an in kind payment to the local church officials of ten percent of the agricultural harvest of the season) has to be exactly the same as the share the peasant keeps (2nd book, Art. 48 §6). Rulers had to be informed about the estimated quantity of the harvest in advance, otherwise they could make their own estimate of the harvest in advance, otherwise they could make their own estimate of their subjects’ dues.

2. Gentry and Nobility

The intermediate level of the feudal societal order was the gentry, i.e. lower-ranked nobles like knights, officials (“Ministerialen”) of the noble state ruler (like reeves) and also those counts and barons who ruled over a feudal estate that was not “reichsunmittelbar” (directly subordinate to the Emperor) but was given to them by a duke or prince. Those medium ranked nobles (the gentry) usually administered their territory under a higher-ranked noble. For example, counts originally served as vassals of dukes with responsibility for a particular county of the duchy. As such, they

---

16 In the south west of the HRE, rulers found arrangements to deal with it, either by demanding several types of fees and compensation payments for permission to emigrate or by bilateral agreements with neighboring rulers that for each serf migrating to the territory of the neighbor they get one of the neighbor’s serfs (Blickle, 2006). In the north, by contrast, they took measures to further punish migrants in order to restrict emigration, e.g. they made agreements with other rulers to send back strangers from other states who didn’t have a an official dismissal allowance from their former ruler—but with apparently limited success (Blickle, 2006; Peters, 1995).
17 The reader is referred to Blickle (2006) and Buszello et al. (1984) for detailed accounts of the Peasants’ War.
18 An overview of the history of German peasant revolts and uprisings in general, including several case studies is given by Blickle (1988, 2006) and Franz (1976).
were responsible for the collection of dues and taxes in their feudal estate. These intermediaries could engage in rent-seeking (North and Thomas 1971, North et al. 2009), keeping a certain amount for their own purposes and passing the rest to the overlord. They had to provide soldiers for the wars of the overlord in return for his protection. Hence, the principal-agent problem between them and the households discussed above, was relevant to the relationship between the overlords and the gentry. If the gentry could not appropriate enough taxes from the serfs (or overtaxed the households) the amount that the overlord received from the gentry was also reduced. Furthermore, as the local gentry had better information about the agricultural than the overlord, there is an additional principle-agent problem between gentry and nobility. The first has an incentive to cheat the nobility in order to retain a higher share of output for themselves. Of course, the incentive to conceal tax revenues increases as agricultural output, and the amount that is available for appropriation, decreases. This increases the severity of the principal-agent problem between the nobility and the gentry.

Territorial states saw these intermediaries as necessary to collect taxes, but also as a cost factor, aware that information asymmetries led to rent-seeking. As Bloch (1966, p. 134) wrote, the emergence of absolutism was “to protect rural communities, ripe material for taxation, from intemperate exploitation by their landlord”.

3. Emperor and Nobility

At the top of the feudal order was the Emperor of the HRE, who was usually also the king of Germany. He was the supreme overlord and granted feudal estates to his vassals, the “Fürstliche Häuser” (princely houses). This originally meant dukes, princes, bishops and archbishops. They also had the right to ‘subcontract’ parts of their estates to lower-ranked nobles for administration (subinfeudation).20 The Emperor also granted city rights (making cities directly subordinate to the Emperor), and had the right to reallocate estates from disloyal or deceased vassals. In exchange for the feudal estate and troops for war and dues from the nobles (the ‘Reichsmatrikel’) he guaranteed security of their rights over the estate. The Emperor also had territories that he

20The fact that the vassals had the right to give away parts of their estates to lower-ranked nobles also led to a decrease in the power of the Emperor over time. This was because, within the feudal hierarchy, a noble was subordinate only to his immediate overlord and not to those at higher ranks.
ruled directly. In those territories, the Emperor usually installed officials like reeves to collect taxes, administer the law and uphold order. Here again, the relationship between nobility and Emperor was characterized by a principal-agent problem, and again, the initial information problem between gentry and serfs determined the amount of dues, taxes and troops the Emperor could extract from the nobility. Most of the time the nobility had a better bargaining position than the Emperor as, especially during the Middle Ages, the Emperors did not directly control a large area. Furthermore, the German king was traditionally elected by the leading princes (the electors). Hence, he depended on the loyalty and favor of the most powerful territorial rulers. This allocation of power between the princes and the Emperor lead to a decline in his power during the medieval period and a decentralized, highly fragmented political landscape. \footnote{The Golden Bull of 1356, the so-called constitution of the HRE, officially settled the election procedure of the king by the electoral college and confirmed the rights and privileges of the electors. This made those seven (and later up to nine) electors the most powerful rulers of the Empire.}

III. Model

The purpose of the model is to connect information costs in a completely coercive society to tax capacity, as in Mayshar et al. (2017), and from there to connect the geographical size of rural states and migration to cities. We will employ a two-sector model of agriculture and proto-industry. To be consistent with the historical setting we will not allow for non-coercive institutions (see Acemoglu and Wolitzky 2011; Boix 2015), and only a negligible share of agricultural output is traded via markets (Ogilvie 2001). We will outline a static analysis before turning to the system dynamics.

The optimization problem of our states is very complex, so that we constrain ourselves to the most simple notation, standard letters, omit explicit functional form, and explain our concepts mostly by comparative statics. \footnote{Consider any function \( f(x) \) that is differentiable twice. We will use a shortcut to ease notation using \( f(x \uparrow) \) if \( \frac{df}{dx} > 0 \) and \( f(x \downarrow) \) if \( \frac{df}{dx} < 0 \).} In general, states maximize tax revenue over an infinite time horizon. They aim to extract all of their subjects’ output above subsistence. \footnote{The idea that the taxes were so high that peasants were kept at subsistence can be found both in Smith (1776) and Malthus (1798), and is also a feature of Mayshar et al. 2017.} They can do so by allowing their subjects to move to cities, adjusting their urbanization rate \( u \in (0, 1) \). States can also conquer other
states’ territories, which will affect their geographic size \( a \), their average Ricardian land rent \( r \), and the observability of their agricultural output \( N \). Attacking other territories and defending against attacks come with adjustable costs \( V \). States can also allocate parts of their budget to maintaining interior order \( G \). These costs include tax administration, but also collecting information on tax cheaters, quelling uprisings, preventing subjects from fleeing the state or moving around the state against the state’s interest, acquiring subjects from over states, and rudimentary poor relief.

Decisions of state budgets and strategy are taken discretely for any year \( t \). States have a common discount factor \( \delta > 0 \) so that the optimization is given by

\[
\max_{u, d, Y, N, G} \sum_{t=1}^{\infty} \left( \frac{T_t}{(1 + \delta)^t} \right) \quad \text{s.t. constraints}
\]

which are described in more detail now.

1. General Model of the Economy

We will drop state and period subscripts for ease of notation, wherever possible. Consider any state that produces agricultural output \( R \) and output from proto-industry \( P \), so that \( Y = Y_P + Y_R \).

The state is endowed with common labor \( L \), which is split between rural \( L^R \) and urban \( L^P \) labor stock, depending on the urbanization rate \( u \), \( L^P = uL \) and \( L^R = (1 - u)L \). Agricultural output depends on common technology \( A_R \), factor inputs \( L^R \) and soil \( S \), which can be substituted at elasticity \( \alpha \), so that \( Y_R = A_R L^R \alpha S (1 - \alpha) \). Output of the proto-industry depends on common technology \( A_P \) and manual work \( L^P \) at diminishing returns \( \beta < 1 \), so that \( Y_P = A_P L^P \beta \). There is a common information technology \( A_T \in (0, 1) \) to collect taxes and assess agricultural output.

States collect these taxes in the form of goods, or via direct labor services (North and Thomas 1971, Volckart 2002, Mitterauer 2004). Subsistence in cities is higher than in the countryside as cities do not produce food and transport is costly, \( s_P > s_R \). Therefore, tax income \( T \) is a function of \( T^P(A_T \uparrow, Y_P \uparrow, s_P \downarrow) \). Subjects naturally prefer to live in cities (which we will show later). We can therefore solve for the urbanization rate that maximizes tariff revenue, which is found where the additional tax from a urban labor supply is offset by the loss from its higher costs of subsistence and the loss to the rural labor supply, \( u(\frac{\partial Y_P}{\partial L^P} \uparrow, \frac{\partial Y_R}{\partial L^R} \downarrow, (s_P - s_R) \downarrow) \). States face costs
$V > 0$ to protect their borders using common military technology $A_V^{24}$ These costs increase with geographic size $a$, but have decreasing marginal costs per area $[\text{Bean}, 1973]$. The investment in one period has consequences for the following periods. Castles need to be maintained, and unemployed soldiers would find employment as rowing bandits, so that $V_t(A_V \downarrow, a \uparrow, V_{t-1})$ with $\frac{\partial^2 V}{\partial a^2} < 0$ and $\frac{\partial V_t}{\partial V_{t-1}} \geq 0$. This explains that there will be some states which will maximize tax revenue by minimizing the costs of defense, e.g. by building a wall around the city itself, setting $u = 1$ and not having any endowment of soil $S$. These are city states.

2. The Problem of Agricultural Taxation

States having $u < 1$ use soil as an input factor. Following $[\text{Mayshar et al.}, 2017]$, states have incomplete information about soil quality and depend on estimates of agricultural output. Therefore, the state will organize tax collection in its territory by building a hierarchy. This hierarchy features distinct groups of households, which are groups of individuals. Rural households are only connected to the state only via a set of individuals, the intermediaries. Any rural household $h$ is part of a set of households $H$ that owes taxes to the tax official, or lord, $g_1$ at the lowest level of intermediaries $l_1$, which contracts the land from. In this way, various layers on other layers $l_2, ..$ various intermediaries $g_2, ..$ are interposed between the state and all its rural households $H$, $h \in H^l_{g_1} \subset H^l_{g_2} .. \subset H$. Using adaptive expectations about the quality of the soil, the lords or officials parcel this land and assign it to rural households. They can assess average Ricardian land rent $r$. However, the complexity of the interaction between weather and terrain affects fields in any period $t$ in ways that are beyond their understanding $^{25}$

$S_{ht} = r_h + \omega_{ht}$ while $\lim_{t^* \to \infty} \sum_{t=0}^{t^*} \frac{\partial S_{ht}}{\partial \omega_{ht}} = 0$. Households naturally learn about their current soil endowment as they harvest. Anyone else has to rely on incomplete information about the soil quality $^{26}$ Using adaptive expectations, the

---

$^{24}$This argument is in line with coercion, or violence as the source of states, as in $[\text{Olson}, 1993], [\text{Tilly}, 1993], [\text{North et al.}, 2009], [\text{Cenni and Voth}, 2015]$ and $[\text{Boix}, 2015]$ have based their arguments about the dynamics of state building on this aspect.

$^{25}$Imagine two farms, one on the hill, and one in the valley, and strong rain for days. The hill farmer will find it sufficient to dig some temporary channels to help the excess water find its way downhill; the valley farmer will find his crops flooded.

$^{26}$We can neglect Bayesian updating, mostly due to limitations on the tax collector’s learning behavior. How do states learn about their subjects’ soil quality in any period? A scientific model of the link between weather, landscape characteristics, and meteorology, was not available. States cannot learn from their subjects’ words, but they can learn from what they observe, in the form of operant conditioning and social cognitive learning. If tax collectors observe an unexpected increase in some households’ livestock, physical appearance, and living conditions in general, and increase the tax, this learning is part of natural human behavior, and therefore common technology. Learning from peers, e.g. if some
most local intermediary will allocate a plot of land to a household that maximizes tax revenue, depending on the average rent and the subsistence level, \( a_h(r_h \downarrow, s_R \uparrow) \) as it cannot be optimal to keep the households below subsistence. This will not assure that households never starve, as the effects of the weather upon a specific plot are unobserved to anybody but the household, which is not trusted to share the information. Generalizing this point, due to the principal-agent problem on each layer, all layers from the lowest gentry \( l_1 \) up to state level \( n \) depend on own estimates. We assume that any level’s signal about soil quality \( S^* \) is normally distributed around the actual endowment of rural household \( h \) with soil \( S \) in period \( t \). The shape parameter \( N \) represents noise (a decrease in the quality) of the signal. From standard reasoning about information asymmetries back to Akerlof (1970) it follows that the signal gets weaker the further up the hierarchy, so that for any level \( k \) it is \( \forall_k = \{1,...,n\} : S^*_{ht} \sim N \left( S_{ht}, N_{lk} \right) \) while \( \forall_k = \{1,...,(n-1)\} : N_{lk}^{(k+1)} \geq N_{lk}^k \). Any level \( k \) will however use this signal as the basis for taxation of household \( h \), and wish to leave all levels below it with subsistence only, \( T_{hl}^k (Y_{ht}^* \uparrow, s_R \downarrow) \).

What are the consequences of underestimating the soil endowment? Since \( S^*_{ht} < S_{ht} \) it follows that some of the agricultural output cannot be taxed away. If the signal of the lowest level of intermediaries underestimates the soil endowment, this yields a potential rent \( y \) for the households, \( y_{ht}^l (S^*_{ht} - S_{ht}) \) with \( \frac{\partial y_{ht}^l}{\partial S_{ht}} \geq 0 \). This potential rent will be realized by rational agents depending on the probability of being caught cheating and the punishment (following the logic of Becker, 1968). Prosecution of households often ended with subjects being injured and dying, such that prosecution could reduce the supply of labor in the next period. If chances of being caught are high, rural households will reduce their effort during the harvest, leading to a reduction in \( L \). Lords also had the right to punish ‘insubordination, persistent laziness, or deliberate neglect of their duties’ (Whaley, 2012, p. 251), so that this labor reduction was also risky. In any layer, intermediaries therefore have the incentive to keep their agents from realizing rents, and hold on to them themselves. In the long run, it has different effects on the society who is the one extracting rents, but for the tax capacity of the state, it has only
negative ones\textsuperscript{27} The same principal-agent problem is repeated up to the level of the state \( n \), which has the lowest quality of information \( I_{ht} \mid S_{ht}^{*l_n} < S_{ht} \) = \( y_{ht}^{1} + \sum_{k=1}^{(n-1)} y_{ht}^{k} (S_{ht}^{*l_{k+1}} - S_{ht}^{*l_{k}}) \).

Knowing that on average any second period yields rents, long run rents in any state \( r \) relate to the information asymmetries of all rural households in \( H = \{ h_1, h_2, \ldots \} \) on all layers \( l_1, \ldots, l_2, \ldots, l_n \), yielding \( \lim_{t \to \infty} \sum_{t=0}^{T} I_{ht} \sim \{ N_{h_1}^{l_1}, N_{h_2}^{l_2}, \ldots, N_{h_1}^{l_n}, N_{h_2}^{l_n}, \ldots \} \). We can conclude that underestimation of harvests limits the tax capacity of a state by reducing taxes that could be gained from the potential output of household \( h \) in period \( t \) under perfect information \( Y_R \) by the rents \( I_{ht} \mid S_{ht}^{*l_n} < S_{ht} \) = \( T(A_T, Y_{Rl}, S_{ht}) - I_{ht}. \)

Now turn to the case of an overestimation of soil quality, which at any point in time \( t \) can leave any other element of the chain with agricultural output below subsistence after tax collection. In the end, this was mostly true for the households. First, assume that households did not want or could not leave the state—as we will focus on emigration later—so they decided to pay the taxes. One option would have been working on the side to get the taxes from other sources. This was dangerous, as it was highly illegal. Lords often sold households’ extra labor supply to urban traders in form of monopsonies \textsuperscript{[Ogilvie 2001]}\textsuperscript{[1043]}. This included many forms of agricultural goods, and also intermediaries, such as yarn. To uphold Lords’ income from these contracts with traders, the informal labor market was illegal. The illegal labor market can be characterized as an exchange of jobs undertaken by desperate households that often came with a health hazard plus a high risk of capital punishment in case of being caught. Second, households could also resort to violence, e.g. looting granaries. Third, households could starve. All three options had negative effects on households’ ability to provide labor, which we will circumscribe with \( Q \). Households could try to move to a city, or another state. Given that cities also allow their citizens to subsist, due to complete information on output, subjects living in a city cannot be overtaxed. If we imagine our medieval households to be disutility minimizing, they would naturally prefer to live in the town. However, as states use \( u \) as one of their decision variables to maximize taxes, they will only allow this up to the point at which it reduces overall tax revenues. This can render within state urbanization impossible.

\textsuperscript{27}Arguing with Malthus, rents sought by households can lead to a higher population, until the returns to the factor of labor diminish, and emphasize the effect of bad harvests (see also Mayshar et al., 2017, 2015; Voigtländer and Voth, 2013). In case gentry and nobility realize the rents, this can undermine the political stability of the state, and also lead to a decrease in households’ fertility due to rising prices for staple food following Engel’s Law (Engel, 1857).
Concerning migration to other states, we assume that all states are alike in their aim of extracting all of their subjects’ taxable output, so that we can neglect tax competition between states. Consider migration from any state \(i\) to the rural area of another state \(j\), which households perceive to be the most attractive due to its soil endowment and allows immigration due to its marginal product of labor \(\frac{\partial Y_j}{\partial L_j}\). Migration of households to closer states is more probable than long-distance migration for two reasons. First, households need to collect information about the state they contemplate moving to (see Bursztyn and Cantoni [2016]). Second, their disappearance is less likely to be noted if it only takes some hours to reach the border (Volckart [1997, 2002] [Blickle, 2006]). Therefore, fleeing time \(d\), the probability and severity of the punishment when caught, and the perceived information asymmetries explain why migration from the household to the safe border of the destination state is central\(^{28}\). The net migration \(X\) from any territorial state \(i\) to any other territorial state \(j\) can be spelled out as

\[
X^R_{ijt} = \sum_{h \in i \rightarrow h_2 \in j} \left( N_{h_1}^i \uparrow, N_{h_2}^j \left( \frac{\partial R_j}{\partial L_j} - \frac{\partial Y_i}{\partial L_i} \right) \uparrow, d_{hd} \downarrow, G_i, G_j \right)
\]

with \(\frac{\partial X^R_{ijt}}{\partial G_i} \leq 0\) and \(\frac{\partial X^R_{ijt}}{\partial G_j} \leq 0\). Destination states could find it either beneficial to stop peasants from immigrating, depending on their marginal product of labor, by investing in \(G\), but could also welcome the arriving migrants by investing in \(G\) and allocating them to a field to harvest for future seasons\(^{29}\). In the absence of labor market regulations, this would only depend on immigrants’ marginal product and their subsistence needs. Following Domar [1970], emmigration also increases the ratio of land to labor and further increases states’ reliance on their subjects.

The most recorded form of outmigration was fleeing to cities, especially Imperial cities. As cities engage in proto-industry using technology \(A_P\), and have perfect information about their citizens, migration to any city \(j\) depends on technologies, marginal product of labor in the city compared to rural areas\(^{30}\) and observability \(h \in i \mapsto h_2 \in j\) :

\[
X^P_{hjl} = \left( N_{h_1}^i \uparrow, \left( \frac{\partial P_j}{\partial L_j} - \frac{\partial P_i}{\partial L_i} \right) \uparrow, G_{il}, G_{jl} \right)
\]

while \(\frac{\partial X^P_{hjl}}{\partial G_{il}} \leq 0\) and \(\frac{\partial X^P_{hjl}}{\partial G_{jl}} \leq 0\).

\(^{28}\) Carneiro [1970] and more recently Schönholzer [2017] go as far as viewing this mechanism as the nucleus of state formation. They claim that the impossibility of fleeing allowed coercive government.

\(^{29}\) What we would today understand as poor relief was not established in German lands before the mid 17th century, nor was the problem of migrant poverty seen as a field of government action (Whaley, 2012, p. 261).

\(^{30}\) Historic literature following Abel [1943, 1953] has focused on these factors, viewing the process of abandoning areas in Central Germany solely as an outcome of wage differentials induced by the Black Death.
3. Government Under Information Asymmetry

We established that states have room to reduce, or avoid, negative effects of asymmetric information by spending on interior order $G$. This would deliver better information on tax cheaters, leading to a reduction in households shirking, but it could also just lead to more innovation in tax avoidance. States could also spy on subjects planning to flee the country, or deport unwanted immigrants. They could use police to suppress uprisings. It has also been recorded that agents were sent to collect anyone without a master from neighbouring territories (Whaley, 2012, p. 252), which is essentially another form of investing in $G$. ‘Peuplierungspolitik’ (populationist policies) (Whaley, 2012, p. 263), most prominently affecting religious minorities, were an outcome of this problem (see e.g., Hornung, 2014, for a later example). These costs $G$ are the sum of the costs for all households, $G_{rt} = \sum_{h \in H} G_{ht}$. For any household $h$, spending is given by the characteristics of the household itself, but also all possible migration targets $h_2, \ldots$, so that $G_{ht}(A_V, A_R, A_C, N_{h_1}^{l_1}, \ldots, z_{h_1}, \ldots, G_j, \ldots, N_{h}^{l_1}, N_{h_2}^{l_2}, \ldots, N_{h_2}^{n_2}, \ldots, z_{h_2}, \ldots)$. Similar to $V$, investment in one period creates maintenance costs for future periods. Collecting information on emigration and tax avoidance builds on established networks of trustworthy spies, so that aggregate $G$ is given by $G_t(\sum_{h \in H} G_{ht} \uparrow, G_{t-1})$ while $\frac{\partial G_r}{\partial G_{t-1}} \geq 0$.

The overall effect of overestimating the soil quality in period $t$ can be given by the possible tax under perfect information less the negative impacts on the households that stay and the effects of emigration to all other countries $J$, so that $[T_{ht} | S_{ht}^{l_h} > S_{ht}] = T(A_{Tt}, R_t, s_t) - \frac{\partial R_t}{\partial Q} - \sum_{j \in J} X_{jt}^r$. If these costs are ignored, they can undermine the state’s existence. The two types of government spending we identified, $V$ and $G$ both have to be financed by taxes. If they cannot be financed, states are bankrupt, iff $T_t < V + G \Rightarrow \sum_{t=0}^{\infty} T_t^* = 0$.

This yields that

**Proposition 1.** States with lower observability of agricultural output are left with a lower amount of taxes, ceteris paribus.

Due to the properties of the normally distributed signal we find that

**Proposition 2.** States with a lower observability of agricultural output face a higher risk of bankruptcy.
Now turn to the long run implications of this problem. Imagine the survival of a feudal state as a continuous struggle of the ruling family to raise an heir to marriage age, and to find an adequate match (Stone [1961]). In the tradition of Gale and Shapley ([1962]), this matching process requires a certain number of possible partners, and an ordered list of preferences for all partners. The German high nobility was relatively closed, which allowed marriage market participants to be well informed about what is on offer (Spieß [1993] and Hurwich [1998]). This gives us the proposition that other participants on the marriage market would notice their problems with efficiently taxing their subjects, moving them down their preference list on the marriage market, so that

**Proposition 3.** States with lower observability of agricultural output are inferior on the marriage market

4. War Over Territories With Information Costs

![Stylized example of two states competing for territory. The plot on the left shows the income/budget of the states over time. The right visualization displays the observability of soil quality in two states, before and after i’s attack on the southeastern plot.](image)

**Figure 3: Stylized example of two states competing for territory. The plot on the left shows the income/budget of the states over time. The right visualization displays the observability of soil quality in two states, before and after i’s attack on the southeastern plot.**

What explains war? Consider state budget, and keep in mind that \( V \) comes with increasing returns to scale. As outlined in fig. 3, under certain conditions, state \( i \) will find it profitable to conquer territory from \( i \). He would invest in \( V \) above the budget the defendant would have to invest in keeping the territory. If successful, the aggressor would increase its size \( a \), which would also affect
its average Ricardian land rent $r$. The aggressor would choose exactly the territory that yields the best combination of land rent, and observability, deduced by the one time costs of the attack and the recurring costs of defense. Depending on the magnitude of the increasing returns, a geographically larger state might maximize its long-run tax revenue by taking over territory that reduces its average land rent, and also its average observability. The higher the information costs of $i$, the less funds can be raised for defense. If increasing returns to scale become very large in magnitude, as implied by Tilly (1975; Gennaioli and Voth, 2015) for 16th century onwards, this allows geographically larger and less observable states to overtake even more observable territories. In the long run, this yields

**Proposition 4.** States with poor observability of agricultural output are geographically smaller, ceteris paribus.

This shows that there are many channels via which information costs affect states, including the risk of rent seeking intermediaries, mass starvation, outmigration, civil unrest, urbanization, and war. We have linked this to geographical variables and the state of technology, which we assumed to be common across states. The central outcome of this model is that it is costly to states to solve problems caused by asymmetric information, and that in the long run this affects the survival of the state.

**Proposition 5.** Any state with a higher observability of agricultural output than any other state also has a higher probability of survival.

Finally, it is well established that asymmetric technological and institutional changes in favor of proto-industrial technology, accompanied by a period of wars, flight to cities (Dincecco and Gaetano Onorato, 2016), and also the ‘military revolution’ led to an unprecedented urbanization after 1500 (Tilly, 1993; Voigtländer and Voth, 2013; Dittmar and Meisenzahl, 2017; Bosker et al., 2013; Boix, 2015). This hints at a reduction in the diminishing returns to labor in cities, $\beta \downarrow$, and also in the relative defense costs $V$ for cities vs. territorial states. Territorial states would therefore increase $u$ (reducing the role of soil, and reducing the need for hierarchy as population decreases), and city states would allow more immigration.

**Proposition 6.** The predictive power of agricultural observability diminishes over time, especially after the structural changes around 1500.
IV. Data

1. Dependent Variable: State Size

To calculate the size of a state, we digitized maps of the “reichsunmittelbare Territorien” (territories directly subordinate to the Emperor) of the HRE (without its Italian parts) as provided in the atlas by Wolff (1877). These were the most detailed maps we could find. Furthermore, Wolff drew maps for the periods of decisive historical events of the HRE. These dates are 1250 (collapse of the Staufer dynasty), 1378 (peak of political fragmentation), 1477 (Peace of Nancy), 1556 (Peace of Augsburg), 1648 (Peace of Westphalia), and 1789 (outbreak of the French Revolution).

The maps contain the names of the territories, and their borders. It includes all types of states in the Empire, i.e., city states (Imperial cities), large territorial states (kingdoms, duchies, principalities, margraviates, counties etc.) and ecclesiastical states (bishoprics, archbishoprics and monastic territories). However, each map contains white and unnamed territories (either because the name of the territory was not certain or because the territory or territories were too small to be included in the map). We tried to populate these white areas by comparing the different maps (as sometimes a territory is included in one map but not in another one) and we also overlaid the maps with Google maps. This enabled us to identify the territories based on the cities located within them. We were also able to considerably reduce the white areas in the maps but still, especially in 1477—when the map is less detailed than in the other years—some white areas containing very small states or that were divided between several states in a complex manner, remain. Nevertheless, as far as we are aware, ours are the most detailed and comprehensive digitized maps of the states of the HRE currently available.

To validate and cross-check the maps and the included territories, we compared them to several

---

31. To define only territories that were directly subordinate to the Emperor as states seems to be the consensus among German historians the reason is that only those states had a degree of independence somehow similar to modern sovereign state. States not directly subordinate to the Emperor were subordinate to a higher ranked ruler of another state (e.g. a duchy), and the rulers of those state received them as a feudal estate (“feud”). However, their power over the territory was limited. Another concern with the maps is whether the de jure situation was consistent with the de facto situation. There could for example be territories that were not directly subordinate to the Emperor but nevertheless were de facto independent. In Appendix A.1.4. we describe in detail who we decided when this was the case and also discuss some examples of states where this was an issue.

32. A detailed historical overview of these critical points of Central European history is given in section A.1.3. of the Appendix.
other maps of historical states in the HRE, including those of Darby and Pullard (1978); Stier et al. (1956); Andree (1886), or Baldamus et al. (1914). Furthermore, we consulted the “Historisches Lexikon der deutschen Länder” (Historical Encyclopedia of German States) (Köbler 1988), a comprehensive and reliable source that provides a historical overview of each German state from the Middle Ages until the late 20th century, including their inception and downfall, the reasons they disappeared, their legal status and name changes. We also consulted the first volume of the “Geschichte der deutschen Länder” by Sante (1964), a monograph about the history of the German states during the medieval and early modern period, that also includes detailed histories of all territories. We used these publications to verify their existence and location. We further checked that they were correctly classified by type, e.g. as a duchy or county.

Errors as to name, type of state or omission of an existing state occurred sometimes. Such problems mostly arose in the case of small states on which information is limited even today (typically some “Herrschaften”, states ruled by a baron or an imperial knight), when there were several territories with the same name (e.g. “Limburg”) or for a few of Imperial cities in the Alsac-Lorrain region which Wolff forgot. However, we were able to resolve almost all of these issues, sometimes by consulting additional sources such as books by local historians.

Another difficulty was determining the start and end point of a states’ independence. The latter was problematic, when, for example, a states was split up between the sons of a ruler and three family lines ruled over three different parts of the former territory. Here, Wolff not always correctly recorded the division of the state, which we resolved. Sometimes, after a ruling dynasty died out due to a lack of a male heir (or after a war about its heritage) a territory was partitioned between several other rulers. In this case, we decided whether to assign the territory to the state that had the majority of rights or whether it remained an independent state (when there was no clearly

33To validate the city states drawn in the maps we also consulted Cantoni (2012) and the “Deutsche Städtebuch” (Handbook of German cities) (Keyser and Stoob 1939–1974) an encyclopaedia containing information on the history of each German city from its foundation/first mentioning until the 20th century.

34Another case was that of the Imperial city of Friedberg and the burggraviate of Friedberg, located around a castle next to the city. The latter was a very small county around the castle of Friedberg that was involved in various conflicts with the nearby Imperial city. Wolff does not include both territories before the 1789 map, where he drew a territory called Friedberg and marked it as an Imperial city. We split this territory between the Imperial city and the burggraviate from 1250 to 1378. In 1477 the Imperial city lost its independence (it was under the control of the burggraviate then for most of the time) and thus, we assigned the whole territory to the burggraviate in the later maps—the burggraviate existed until 1806.
Overall, we identified 730 independent states, including 81 city states, 89 ecclesiastical territories (bishoprics, archbishoprics and monastic states), and 560 secular territorial states. The latter group consists of two kingdoms, Bohemia and Prussia, 48 duchies, 80 principalities\(^\text{37}\) 16 republics (all of them in today’s Switzerland), 217 counties\(^\text{38}\) and 180 “Herrschaften” (territories ruled by “Freiherren” (barons)). Furthermore, there were seven Imperial territories (directly controlled by the Emperor), among them were six “Landvogteien” (Grand Bailiffs) and one territory, the Stauffian lands, controlled by the Stauffian Emperors during the 11\(^{\text{th}}\) to 13\(^{\text{th}}\) century. There are also four territories that were occupied by the Swedes after the Thirty Years’ War. Finally, there are nine electorates (among them three archbishoprics already counted above), which are considered to be the most powerful states of the HRE and are hence considered an own category.\(^\text{39}\)

Figure A.2 provides an overview of the HRE and its territorial and city states in each of the six years for which we have a map from Wolff (1877).\(^\text{24}\)

\(^{35}\)This was the case, for example, for the county of Sponheim which had a constantly changing political history. Details on this case and how we solved it can be found in Appendix A.1.2.

\(^{36}\)A lack of clarity about when a territory ceased to be an independent state typically arose also because Wolff (and other historians) followed a tradition of drawing important states (like e.g., the duchy of Berg) as independent (“reichsunmittelbare”) states even when they were de facto ruled by other nobles, as was the case for the united duchy of Kleve-Jülich-Berg which was split up again after armed hostilities over the different parts, with one part (the duchy of Kleve and the counties of Mark and Ravensberg) falling in the hands of the margrave of Brandenburg and another part (the duchies of Berg and Jülich) coming under the control of the duchy of Pfalz-Neuburg. In these cases we diverge from the map and make these territories part of Brandenburg or Pfalz-Neuburg, respectively.

\(^{37}\)Apart from principalities, we also classify the following states into this category: Nine “Landgrafschaften” (landgraviates), 17 “Markgrafschaften” (margraviates) and two Princely counties (the Principely county of Burgundy and the Principely County of Tyrol). The reason for this is that the rulers of those states (the margrave, the landgrave etc.) were considered to have the same rank as princes (although their names refer to their origins as counties).

\(^{38}\)The 226 counties subsume the following territories with “county” in the name: Four “Pfalzgrafschaften” (county palatinates). In general, the rulers of those territories (the palatinates) were considered to be of a higher rank than ordinary counts (in the case of a “Pfalzgraf” (Palatinate)). One of these county palatinates, the “Pfalzgrafschaft bei Rhein” (County Palatinate of the Rhine) had the status of an electorate from the middle of the 13\(^{\text{th}}\) century (and was thereafter called “Kurfürstentum Pfalz” (Electorate of the Palatinate)). Thus, it still was called a county palatinate but actually was one of the most influential and powerful states within the Empire. Then, there are also six burggraviates and 207 ordinary “counties”. It is important to note that counties were fairly heterogeneous regarding their size, and political importance. The county of Württemberg, for example, for a long time the largest county of the Empire (before it became a duchy in 1495), was larger than some of the principalities or duchies of the time and also had higher tax revenues than some of those higher-ranked territories. Hence, one should not assume counties to be less important or smaller than duchies or principalities.

\(^{39}\)The official title of those states differed. Some of them were called “Kurfürstentümer” (electoral principalities) some are margraviates or county palatinates and the Habsburg monarchy called itself “Archduchy of Austria”.
2. Main Explanatory Variable: Caloric Observability Index

To proxy observability, we propose an index that measures divergence from perfect observability as proposed in the theoretical framework. This measure of observability of agricultural output is based on the caloric suitability index developed in Galor and Özak (2014) and Galor and Özak (2015). This index provides the average caloric yield per hectare per year for each grid cell on a resolution of 300 arc seconds (0.083 degrees or around 85 km$^2$). The average is derived from the caloric suitability of all 49 crops for which the Global Agro-Ecological Zones (GAEZ) project of the Food and Agriculture Organization (FAO) provides global crop yield estimates and that can be grown in the area of a state (caloric yields > 0). Those estimated crop yields (given in annual tons per hectare) are converted into calories using information on the caloric content of the respective crops, available from the United States Department of Agriculture Nutrient Database for Standard Reference. The commonly used agricultural suitability measures of Ramankutty et al. (2002), or Zabel et al. (2014), report the fraction of each grid cell that is suitable for agriculture in terms of probability. Compared to those standard indexes, the caloric suitability index has several advantages. First, equally suitable land can have very different caloric yields, as land that is suitable for agriculture will not necessarily be suitable for the crops with the highest caloric yields. In a Malthusian subsistence society, the main purpose of agriculture is to feed the population, so the caloric yield is central. Second, the caloric suitability index accounts for the fact that prior to the Columbian Exchange not all of the 49 crops incorporated in the GAEZ database were actually available (e.g. potatoes were not available in Europe). Finally, the index is not endogenous to human activities, since Galor and Özak (2014) calculate the potential caloric yields assuming low level of inputs and rain-fed agriculture (it abstracts from irrigation methods) and agro-climatic constraints exogenous to human activities.

Our proxy for information cost, $C_{\text{Noise}}$, is based upon the ruggedness index by Riley et al. (1999) that is applied to data on the caloric suitability index $CSI$ (not elevation). It is therefore defined

---

41 We use the version of the index that does not include crops with zero productivity in the respective grid cell for the calculation of the average caloric yields.
42 This allows the usage of tools already implemented in QGIS or other GIS software and makes our results easy to reproduce.
for raster data, providing data for row-column-coordinates \((r,c)\). \(C\text{Noise}\) of any state \(s\) is the average of all \(C\text{Noise}\) raster values in the state\(^{43}\). We construct \textit{Caloric Observability Index} by linear transformation using the maximum over all states. This transformation has two semantic advantages. First, it is a positive index that translates to lower information costs, the higher the index. Second, it captures the idea that observability is a relative measure of comparable states that compete with each other; the state with the weakest observability serves as a benchmark.

\[
C\text{Noise}(r,c) = \left( \sum_{i=(r-1)}^{(r+1)} \sum_{j=(c-1)}^{(c+1)} [\text{CSI}_{(i,j)} - \text{CSI}_{(r,c)}]^2 \right)^{1/2}
\]

\[
C\text{Noise}_s = \frac{1}{|\{(r,c)\in s\}|} \sum_{(r,c)\in s} C\text{Noise}_{(r,c)}
\]

\textit{Caloric Observability Index}_s = -1 \left( \max_{t\in \text{States}} (C\text{Noise}_t) - C\text{Noise}_s \right)

For each column \(c\) and each row \(r\), we derive the variance between the caloric suitability \(\text{CSI}\) and that of its neighboring fields. If this variance is zero, measuring caloric suitability of one field would perfectly predict the suitability of neighboring fields, and caloric observability is zero. With an increase in between-neighbor differences, the relationship between factor input and output becomes less observable, and the households’ effort harder to observe. Hence, high values of the COI correspond to low observability and vice versa. To ease the interpretation of the COI, we transform it for the empirical analysis to ensure higher values correspond to higher observability.

Figure 4 provides an overview of the average observability of the caloric yields of each state of the HRE in each of our six sampling years.

3. Other Explanatory Variables & Controls

To limit concerns about omitted variables bias, we include a number of variables to our data set that should capture potentially relevant confounders of state capacity and size. Those are:

\textbf{Agricultural conditions}. A vast body of literature has pointed at soil quality as an indicator for

\(^{43}\)This can be retrieved using the summary statistics tool in QGIS and ArcGIS, given the raster data and polygons on the states.
Note: These figures show the average Caloric Observability Index in each of the territories of the HRE at the different sampling years. After 1500 New World crops become available due to the Columbian exchange and are included in the calculation of the COI. Increasing caloric observability corresponds to increasingly darker shades of green; increasing shades of red denote decreasing caloric suitability.

Figure 4: Observability of Agricultural Output in the States of the HRE
Origins of State Capacity

development (e.g., Diamond 1999; Olsson and Hibbs 2005). For example, von Thünen (1826) and more recently Lindert (1999) and Kopsidis and Wolf (2012) have pointed at the link between urban development and soil quality. Furthermore, the vast majority of the population was employed in agriculture and had to feed the growing urban population which produced all the innovations and proto-industrial activity. Thus, to account for the effect of the level of soil quality on state development, we use the caloric suitability index by Galor and Özak (2014, 2015) that we already have used to construct the observability index. A necessary prerequisite for crop farming was deforestation, which was mostly finished by the 12th century (Wilson 2016). We digitized data on areas still forested (or otherwise non-arable, for example, marsh land) during the Middle Ages, which is available for modern Germany from Schlüter (1952). With this variable we control for the share of a territory’s area that was not deforested by the early Middle Ages. Finally, a growing body of literature is concerned with the effects of specific crops, such as the potato, on various economic outcomes (Nunn and Qian 2011) and more recently Berger (2017). We therefore employ both the pre-1500 and post-1500 specification of the caloric suitability index. The fact that cereals, which can be stored and transported, are easier for rulers to appropriate could also be a factor (Mayshar et al. 2015). We control for this aspect with a variable measuring the productivity advantage of cereals over roots and tubers. Finally, we include the average temperature to account for climatic variations over time that could affect the agricultural output in each state.

Border States. Recently, economic research has found evidence that state capacity within historical and contemporary developing countries varies depending on the remoteness of a region (Olsson and Hansson 2011; Michalopoulos and Papaioannou 2014). Thus, in peripheral areas state capacity might be weaker. Looking at the HRE, it is evident that many of the border states were politically unstable and conflict-prone, and eventually gained independence from the Emperor (e.g. the Dutch Republic, Switzerland, the northern Italian cities etc.). Thus, we created a variable to identify countries that are located on the outer border of the HRE in each of our sampling years, to account for this. This also takes into account spatial effects of outward threats, especially the expansion of France and the Ottoman Empire (see Iyigun 2008).

Disease environment. Acemoglu and Robinson (2001) and Acemoglu and Johnson (2007) proposed that diseases affect outcomes via political institutions. This makes diseases potentially
relevant for our study. We collected data on the location of medieval swamp areas as well as proximity to rivers, trade routes, and Imperial cities, which could have spread germs in the Middle Ages as outlined in Börner and Severgnini (2014) and Voigtländer and Voth (2013). Diamond (1999) has argued that everyday contact between humans and livestock creates resistance against diseases. This was predominant in all regions of Central Europe (Mitterauer, 2004), but shows some variation depending on the ruggedness of the terrain. We also include a variable measuring the average temperature of each state, as it is well known that germs favor higher temperatures.

**Heavy Plough.** Alesina et al. (2013) and Anderson et al. (2016) document a profound impact of the introduction of the heavy plough on gender inequality and city development. Thus, it is very likely that it could also have affected state capacity, e.g. due to significantly increasing the productivity of agriculture within a state that adopted the plough (or adopted it earlier). Higher productivity of agriculture increased agricultural output and therefore the absolute tax basis of a state. We account for the effect of the heavy plough by a variable measuring the fraction of a states’ area that was endowed with luvisol soils, a type of soil that particularly benefited from ploughing.

**Natural Resources.** It is well established that the availability of natural resources such as gold, silver, salt and copper was a decisive factor determining a country’s state capacity and tax revenues. Where minerals could have been exploited, mining was an alternative to agriculture, and rulers could generate high revenues from mining activities (historically particularly true for the Harz area and Saxony). To account for differences in natural resource endowments, we digitized maps of the geographic location of copper, gold, lead, salt (rock salt and potassium salt) and silver. Based on these maps we calculated a variable giving the average distance from 1,000 randomly generated points within a state to the next deposit of those resources. Additionally, we have data on areas within contemporary Germany that were still forested in the Middle Ages and hence provided a supply of wood—one of the most important raw materials in the pre-modern economy.

**Outmigration.** As discussed above, outmigration to Imperial cities posed a vital threat to the financial base of medieval and early-modern states. Thus, we compute a variable that proxies the outmigration opportunities by the average distance from 1000 randomly generated points within a state to the next Imperial city.
Pre-Existing Cultural and Historical Differences. We can account for the effect of a priori cultural differences in the HRE by assigning each of its later states to one of the states existing in 1150 using, again, a map of European states in 1150 AD by Wolff (1877). The states in 1150 largely reflected old, traditional borders of the territories of Germanic tribes (like the stem duchies, which reflected the territories of the Germanic tribes of the Bavarians, Franks, Swabians and Saxons). To address the possibility of pre-existing, deeply rooted factors influencing state capacity in medieval Europe, we include a variable for the area of each state that was already settled in pre-historic times. These areas might have a longer history of statehood or other positive characteristics making them attractive for settlement.

Terrain Characteristics. We also control for the maximum elevation above sea level and average ruggedness of a states’ territory, using the digital elevation model provided by the U.S. Geological Survey’s Center for Earth Resources Observation and Science (EROS). Both factors could affect state capacity because they have an influence on the defensibility of the area of a state. Ruggedness could also have a direct influence on animal husbandry (see Eder and Halla, 2017) other than agglomeration (Kopsidis and Wolf, 2012). Taxation of animal husbandry could be different to taxation of crops.

Trade and Tariff Income. Trade affects our analysis in many different ways. First, trade was a source of revenue, as trading cities were usually wealthy and generated large tax revenues. Furthermore, trade took place along trade routes, rivers and Roman roads therefore rulers could impose tolls on trade routes and navigable rivers within their territories (Wahl, 2017). Tariff income from such road tolls could be significant and made some territories e.g., those straddling both sides of the Rhine, very wealthy. Finally, if a lot of rivers or trade routes were located within a state, it was easier for its citizens (and the ruler) to access commercial centers. Therefore, these states

---

44 After the Migration Period more than four centuries before, the areas in which different Germanic tribes settled have been relatively stable.

45 We can also rule out nationalism as a unifying element within the HRE and a dividing element between different sub areas that would not be captured by tribal areas in 1150. There is wide consensus that nationalism cannot be attributed to Central Europe before the 18th century, if not the French Revolution (Weber, 1976, Anderson, 1983). We conclude from this that the sizes of states were too small for heterogeneous preferences in the spirit of Alesina and Spolaore (1997) or Bolton and Rolando (1997) to limit the growth of states.

46 There is a growing literature documenting the importance of the Roman road network for the long-run development of Europe (e.g., Wahl, 2017). This makes it even more important to account for the Roman road network and its possible effects.

47 The small sizes of states introduce competition between them over trade routes, so that any single state can only raise its overall revenues from tariffs to the level that drives traders to change their routes (Huning and Wolf, 2016).
origins of state capacity profited from better market access and lower transaction costs. We proxy for these advantages with variables measuring the average distance from 1000 randomly generated points within a state to the next Roman road, trade route or major navigable river. We also control for trade fairs, which were identified by Milgrom et al. (1990), and more recently Edwards and Oglivie (2012) as classic example of medieval trade institutions. With respect to access to financial markets, the results of Volckart and Wolf (2006) suggest that there is a strong correlation between the spatial pattern of the integration of commodity markets on the one side, and financial markets on the other. We therefore assume to have controlled for spatial variation of financial integration with the above.

War and Conflicts. Several authors have argued that war and conflicts were a driver for state capacity in Europe, e.g. because of competition between states fostering technological and organizational innovations (e.g. in taxation technologies) (Hoffman 2011; Karaman and Pamuk 2013; Tilly 1975). We construct a variable measuring the number of battles that had taken place within a state between 800 and 1378 AD, normalized by a state’s area. Romer (2009) and Acemoglu et al. (2011) have pointed to the benefits of importing efficient political institutions, which in our historical setting is captured either via trade as a market for ideas, or conflicts. Radical modernization occurs well after the period in our study (also see Mokyr (2011)).

A descriptive overview of the variables in the data set can be found in Table A.1. Definitions and the sources of all the variables can be found in the Online Data Appendix (Appendix A.2). The maps on which we base our geographic variables are in section A.4 of the Appendix.

V. Empirical Analysis and Results

1. Caloric Observability and the Financial Capacity of States

We expect a significant and positive statistical relationship between caloric observability and the financial capacity of a state (proposition I) and test this empirically. Following Cantoni (2012) we proxy the financial capacity and economic and military power of a state by its contribution (in
origins of state capacity

guilder) to the Imperial war tax (“Reichsmatrikel”) in 1521 [48]. The Reichsmatrikel contributions are taken from Zeumer (1913). We have matched the territories mentioned in the Reichsmatrikel with the states in our data set [49]. If a state existed in 1521 and 1556, we assigned its Reichsmatrikel contribution to the year 1556 in our data set. If a state existed in 1521 but not in 1556, we assigned its contribution to the year 1477 in our data set. Overall, we could match 236 states [50].

We then run a cross-sectional regression where each state’s Reichsmatrikel contribution is explained by its caloric observability and different sets of control variables. Thus, we estimate the following equation using OLS:

\[
\ln(\text{IMPERIAL\_TAX})_{ic} = \alpha + \beta \ln(\text{COI}_i) + \gamma' \mathbf{X}_i + \lambda_c + \epsilon_i
\] (1)

Where \(\ln(\text{IMPERIAL\_TAX})_{ic}\) is the natural logarithm Reichsmatrikel contribution of state \(i\) of type \(c\) in the Reichsmatrikel of 1521. \(\ln(\text{COI}_i)\) is the natural logarithm of caloric observability of a states’ agricultural output. \(\mathbf{X}_i\) is a vector of different set of controls comprising of the variables introduced above. The set of basic geographic controls is made up of: average distance to a major river, maximum elevation, average terrain ruggedness and a dummy for states located on the outer border of the HRE in that year. Variables controlling for soils and climate are caloric suitability, average temperature, share of luvisol soils, and the productivity advantage of growing cereals instead of roots and tubers. The set of “Economic Factors and Resources” variables includes the average distance to the closest trade route, trade fair, Roman road, Imperial city, copper, gold, iron, lead, potassium salt, rock salt or silver deposit. \(\lambda_c\) are state type dummies (for kingdoms, electoral states, ecclesiastical territories, duchies, princedoms, margraviates, counties, republics and “Herrschaften”), capturing unobserved shocks that might have affected different types of states in a different way and also unobserved historical factors making a certain state a kingdom and another one only a county. \(\epsilon_{ic}\) is the error term.

[48] There are three types of contributions: states had to contribute mounted and foot soldiers as well as a certain contribution in guilders. To monetize the whole contribution we follow Cantonii (2012) and assume—in line with the historical literature—that the pay of a mounted soldier was 12 guilders and that for foot soldiers was 4 guilders and multiply for the number of each type of soldier.

[49] It is known that the Reichsmatrikel list has errors, i.e. it contains states that were not or no longer independent (“reichsunmittelbar”) or for which this status is doubtful. Furthermore, our maps give us information about the states in 1477 and 1556 but not for 1521. Thus, we have to rely on information from Köbler (1988) and other sources to match the states in our maps to those of the Reichsmatrikel.

[50] The average Reichsmatrikel contribution was 629.4 guilders with the minimum being zero and the largest contribution being 11,940 guilders (from the states controlled by the Habsburgs).

[51] The base category remaining are states occupied by the Swedish after the Thirty Year’s War and Imperial territories.
Results are shown in Table 1. They show that, reassuringly, there is statistically and economically significant positive relationship between the Reichsmatrikel contributions and caloric observability. This relationship—while being marginally statistically significant—is almost unaffected by the inclusion of different sets of control variables and implies that, on average, a one percent increase in observability increases the Reichsmatrikel contribution by about 0.17 percent. This positive relationship is presented in Figure 5, showing a partial regression plot of ln(Caloric Observability) for the regression in Table 1 column (4).

Notes. Heteroskedasticity robust standard errors are reported in parentheses. The unit of observation is a state. All regressions include a constant not reported. State Dummies are dummy variables indicating electoral states ("Kurfürstentümer"), kingdoms, margraviates, duchy, princesdoms, counties, republics, "Herrschaften" and ecclesiastical states. The set of basic geographic controls comprises a variable measuring the average distance of 1,000 randomly distributed points within a state to the closest major river, its maximum elevation above sea-level, its average ruggedness and a dummy for states adjacent to the boundary of the HRE. Soil and climate controls include the natural logarithm of a state’s average caloric suitability index, the average caloric suitability for growing cereals relative to grow roots and tubers, the fraction of a state’s area with luvisol soil that benefits most from plowing and a measure for the average temperature in a state. The control variables in "Economic Factors and Resources" include variables measuring the average distance of 1,000 randomly distributed points within a state to the closest Roman road, major medieval trade route, trade fair, gold, copper, silver, iron, lead, potassium salt or rock salt deposit.

directly controlled by the Emperor (i.e., bailiffs and Stauflian territories). The electoral states are not double counted as they are not coded as e.g., duchy, margraviate, kingdom or county palatinate.

52By taking the natural logarithm we lose one observation (Gr. Saarwerden) which has a recorded contribution of zero.
2. Caloric Observability and the Failure and Survival of States

To investigate our theoretical propositions\(^2\)\(^3\) and \(^5\) regarding the relationship of observability and the fate of states, i.e. whether and how a state disappeared, we were able to collect data on 367 events leading to the failure (dissolution/ disappearance) of states, mostly from Köbler (1988) and other sources on regional history.\(^{53}\) We grouped these reasons for failure into seven categories (see Figure. 6). In case a ruler died without a legal male heir, and the territory was either inherited by other parts of the family, partitioned within the family, or inherited by female heir and became part of her husband’s territory, we classified state failure as \textit{in family}. If the state was bought by, gifted to, or voluntarily joined another territory after the last ruler’s death, it was grouped into \textit{ex family}. As \textit{bankruptcy} we classified all state failures in which the state was pawned and the state ruler failed to pay back the debt, so that the state changed owners while a legal ruler was still alive. We also classified all events of \textit{Federal Rule} (the Emperor takes away the right to the feudal estate), and joining the \textit{Swiss Union}. The category \textit{War} we used when the territory was conquered by one ore more foreign rulers. To provide descriptive statistics of the link between observability and state failure, we provide box plots separated box plots of the COI for different categories of

\(^{53}\) The territories that are lost in each of the maps as well as the reason for their disappearance are shown in Appendix Figure A.3.
reasons for failure. They are shown in Figure 6.

In general, the most frequent—and probably most unsystematic—reason for state failure was the death of a ruler without a male heir. This is not surprising, given that fertility of the nobility was generally low. The probability of anybody dying of an accident or a common infection was high. Adam Smith was right that the geography of Switzerland set it on a different path. Consider Figure 6a on the period before 1500 (reasons of state failure in 1250, 1378 and 1477). Most prominently, bankruptcy is the leading reason for failure of states with bad observability, which is in line with proposition 2 from the model. When the ruling family of a state ended without a single male heir, partition or inheritance by other states/noble families could be the consequence, which also includes inheritance by the first daughter’s husband (in the plot: in family). States that were sold or given away, leading to the departure of the ruling dynasty (plot: ex family), were associated with about the same observability, with a few outliers displaying low observability. States that were conquered in wars were on average endowed with lower observability, which points towards the role of the decreasing marginal cost of protection on the victorious side.

Federal rule leading to the end of a state was rare, and so was secularization before the Reformation. After 1500 (Figure 6b), sorting by observability becomes more prominent, distinguishing within and out-of-the-family inheritance. Furthermore, bankruptcy is even more prominently associated with bad observability. However, those states that were conquered show a high observability pointing towards the direction of a regime change, which is a puzzle we will investigate further.

Is observability of agricultural output significantly positively associated with the survival of states during the Middle Ages? States with a high observability of agricultural output should be capable of remaining independent for a longer time due to better defensive capacities, more effective abilities to restrict outmigration, etc. To test this empirically, we run Cox proportional hazard models including all the baseline control variables (but, of course, no year dummies). The results

54 See e.g., Schröter (2007) for an overview.
55 Cummins (2017) shows that during the Middle Ages, nobles regularly died on the battle field and their life expectancy was about 50 years.
56 We estimate the Cox proportional hazard model using the Breslow method for ties. Other methods to handle tied failures like those proposed by Efron would yield very similar results. Those estimations are not reported but available upon request. The results would also hold if we exclude the states who exit the data set because they left the Empire and became part of another state entity (like Switzerland) and because their ruling family extinguished (what arguably should be a random event in most cases). Results are available upon request.
are in Table 2 and suggest that, indeed, caloric observability was significantly positively related to state survival during the Middle Ages, but in the 17th and 18th century. To be precise, during the medieval period a ten percent increase in caloric observability raised the probability of a state surviving by around 0.6 percent.

3. Caloric Observability, the Size of States and the Dynamics of Statehood

We now test our theoretical proposition about the relationship between state size (proposition 4) and observability and the temporal evolution of this relationship (proposition 6). We run pooled OLS regressions using the unbalanced panel data set of states in the HRE as explained above. Our data set includes information on 730 states and for six points in time amounting to 1,925 state-year pairs being our observations. As observability of agricultural output is orthogonal to economic activities, political institutions and human activity—at least in the period studied—reverse causality should not be a critical issue. Nonetheless, there still could be a third (and unobserved) factor positively correlated with both caloric observability and political fragmentation. We address this potential bias by including several control variables, which were introduced in the previous section, in the regression specification. In addition to the control variables, we include year fixed effects to account for temporal shocks that affect all of the HRE equally, and we also include eight state type dummies. Thus, to identify our effect we only exploit variation in observability and state size within the same year and within the same types of states. To be precise, we estimate variants of the following regression equation:

\[
\ln(STATEAREA)_{ic,t} = \alpha + \beta \ln(COI_{i,t}) + \gamma'X_{i,t} + \delta_t + \lambda_c + \epsilon_{i,t}
\]  

(2)

Where \(\ln(STATEAREA)_{ic,t}\) is the natural logarithm of the area in km\(^2\) of state \(i\) of type \(c\) in year \(t\). \(\delta_t\) are year dummies. The rest of the equation is defined as in equation 1. In robustness checks, we include dummy variables for the states to which a certain territory belonged in 1150 AD, dummy variables assigning each historical state to its modern-day equivalent, and variables reporting certain characteristics (e.g., area, soil quality or observability of agricultural output) of neighboring states.\(^{37}\)

Later in the empirical analysis, we want to identify the temporal evolution of the effect of observability of agricultural output on state size. We estimate equation 2 as cross-sectional equation, separately for each year. Furthermore, we interact the caloric observability with the year

\(^{37}\)We assigned a state to those state in 1150 or contemporary country in which the majority of its area is located.
dummies and estimate equation 3:

\[
\ln(\text{STATEAREA}_{i,t}) = \alpha + \sum_{t \in \Gamma} \beta_t \ln(\text{COI}_{i,t}) \cdot \delta_t + \gamma X_{i,t} + \delta_t + \lambda_c + \epsilon_{i,t} \tag{3}
\]

Where \( \ln(\text{COI}_{i,t}) \cdot \delta_t \) is the interaction of the COI with year dummies, and all other variables match those in equation 2.

First, we estimate equation 2 to statistically test the relationship between observability of agricultural output and state size. Results of the estimations are reported in Table 3. We start with a simple baseline specification only including year fixed effects and basic geographic control variables.

Caloric observability is highly statistically and economically significant with a one percent increase in observability increasing state size by around 0.5 percent. From columns (2) to (6) we add progressively more sets of control variables, to look how the coefficient reacts to the inclusion of covariates. In column (2) we add soil and climate controls, and the coefficient only decreases slightly. In column (3) we add variables proxying economic factors and resources. These variables decrease the coefficient of observability, but it remains economically and statistically significant. The inclusion of battles per state area in column (4) has virtually no effect on the results and the battles themselves are not significant. In column (5), nine state type dummies are added to further reduce unobserved heterogeneity.

However, this again leaves the coefficient of caloric observability almost unchanged. In columns (7) and (8), we lose some observations, as we restrict the sampling area to the extent of the HRE in 1150. We do this, by including dummy variables that assign the territories of the HRE to the state to which they belonged in 1150 AD. As explained in the previous section, this is to account for pre-existing cultural differences, as the states in 1150 largely reflected the traditional territories

58With regard to the control variables, several interesting results emerge from this specification. For example, distance to the closest Imperial city is significantly positively associated with state size, pointing to the fact that outmigration may indeed have played an important role for the tax capacity of feudal states. Another interesting result is the significant positive effect of battles per state area and the negative and significant coefficient of distance to copper, iron, lead and potassium salt deposits. These indicate the importance of natural resources and war for the capacity of states. The significantly positive effect of maximum elevation also points towards defensibility of the area as an important factor. Finally, caloric suitability itself is positively related to state size, although the estimated coefficient (0.091) is much smaller than that of observability. Thus, it is not only the observability of agricultural output, but also the productivity of agriculture that matters, but observability seems to be much more important.
of Germanic tribes. The coefficient of caloric suitability further decreases but remains significant suggesting that a one percent increase in observability raises state size by around 0.13 percent. Finally, in column (7), the sample is restricted further to historical states within the borders of contemporary Germany, as we control for the area (in m²) within a state that was already settled in pre-historic times (and hence, might have a longer history of statehood) that was still forested or consisted of swamps and flood plains in the Middle Ages. None of these variables stop caloric observability from being significant, although both forest areas and early settled areas show a significant positive effect. The coefficient remains about 0.25, and hence, increases again, when compared to column (6).

Notes. Standard errors clustered on state-level are reported in parentheses. The unit of observation is a state. All regressions include a constant not reported. State Dummies are dummy variable indicating electoral states (“Kurfürstentümer”), kingdoms, margraviates, duchy, princedoms, counties, republics, “Herrschaften” and ecclesiastical states. The set of basic geographic controls comprises of a variable measuring the average distance of 1,000 randomly distributed points within a state to the closest major river and city state, its maximum elevation above sea-level, its average ruggedness and a dummy for states adjacent to the boundary of the HRE. Soil and Climate controls include the natural logarithm of a state’s average caloric suitability index, the average caloric suitability to grow cereals relative to grow roots and tubers, the fraction of a states area with luvisol soil that benefits most from plowing and a measure for the average temperature in a state. The control variables in “Economic Factors and Resources” include variables measuring the average distance of 1,000 randomly distributed points within a state to the closest Roman road, major medieval trade route, trade fair, gold, copper, silver, iron, lead, potassium salt or rock salt deposit.

We then conduct checks to ensure that our baseline results are sufficiently robust. The results are in Table 4. First, we investigate the effect of modern country dummies on the preferred baseline specification (Table 3, column (5)). The estimated coefficient, including those contemporary

59 The HRE spanned 13 contemporary countries. These are Austria, Belgium, Switzerland, Czech Republic, Germany, France, Hungary, Italy, Lithuania, Liechtenstein, the Netherlands, Poland and Slovenia. In the regression we include 12
countries is reported in Table 4, column (1) and shows that the coefficient of observability only decreases slightly when these dummies are included. This suggests that unobserved heterogeneity connected to larger political entities (some of which were created during the existence of HRE e.g., Switzerland) does not decisively influence the effect of caloric observability.

Second, in column (2), we account for the fact that not all land in a state was either settled or suitable for agriculture, so considering the whole area of a state might introduce bias. Thus, we subtract from the overall area of each state those areas with forests, swamps, flood plains, lakes, estuaries and coastal marsh, to use this variable "Settled area" as dependent variable. As information on these areas is only available for contemporary Germany, the sample is again reduced to historical states within modern Germany. Again, the coefficient becomes smaller in magnitude but remains significant.

Third, in column (3) we show what happens if we take into account that, due to the different size of the states, some variables, like ruggedness, or caloric observability, that are calculated based on differences between the data points of the underlying raster data, could be mechanically higher in larger states. Thus, we inversely weight each observation by the number of ruggedness data points that are located within the state. Results are virtually identical.

Fourth, in column (4) we include a variable measuring the number of separated territories that make up a state. The medieval HRE was made up of non-contiguous areas. States with highly fragmented territory will have higher tax collection costs, information and defense costs might be larger, and it could be less susceptible to take over. However, this does not change the coefficient estimate significantly. The next three columns (5-7) show what happens if one estimates the preferred baseline specification using different variants of the caloric observability and state size measure. In column (5), we employ caloric observability and state area in levels instead of natural logarithms. The resulting coefficient is statistically and economically significant. Therefore, the results are not driven by taking the natural logarithms of both variables.

In column (6) we estimate the baseline regression using a caloric observability index also taking into account plants that become available only after the Columbian Exchange.

Notes. Standard errors clustered on state-level are reported in parentheses. The unit of observation is a state. All regressions include a constant not reported. Baseline controls include year and state type dummies, the basic geographic, soil and climate, economic factors and resources controls as well as battles per area.
In column (7) we use a version of the caloric observability index computed under the assumption that only the crop giving the highest caloric yield is actually planted. This is winter barley in all states. Both times, the estimated coefficient is similar to that obtained in Table 3 column (5).

Finally, in column (8) we conduct a placebo-test. We only consider the years prior to 1556 (that is 1250, 1378 and 1477) and test if the difference in caloric observability before and after the Columbian exchange has explanatory power—which should not be the case. Reassuringly, these differences do not explain state size prior to 1500, making it unlikely that our results emerged by chance.

Another concern with the baseline estimates could be that not only characteristics of a certain state itself matter for its capacity. As states compete for labor and territory, characteristics of surrounding states are relevant. Thus, we take the baseline regression specification and add variables capturing relevant characteristics of a state’s neighbors. Results are reported in Table 5 where we add an additional set of neighbor characteristics to the baseline specification in each column. All in all, while neighbor characteristics somehow reduce the size of the coefficient of caloric observability to about 0.16, this is still a large and economically and statistically significant effect. Interestingly, the results imply that neither the caloric suitability nor the caloric observability of the neighbor states has a significant impact.

However, states surrounded by small states are significantly larger than states surrounded by large states (as shown by the negative and significant estimate of the neighbor states area and the positive coefficient of the number of neighbor states). It also seems to be the case that states were larger when their neighbors did not have access to nearby major rivers while the opposite is true for access to resources. Thus, states have profited from having resource-rich states as neighbors, but were better off if their neighbors were further away from important transportation networks.

One important implication of our theoretical argument is that caloric observability should only matter for state size during the medieval period as later on, the scale effect becomes more and more important. To see whether this is the case, we run two types of regressions.

First, we interact the caloric suitability index with year dummies and look at how the effect of
caloric observability develops over time (Table 6). We find that, while the interaction terms are predominantly significant, in line with our expectations, the coefficient notably declines after 1556.

Second, we run separate cross-section regressions for each of the six years in our data set (Table 7).
Here, the coefficients of caloric observability are highly statistically significant and vary between 0.2 and 0.33. Again confirming our theoretical reasoning, in 1648 and 1789 the coefficient of caloric observability is not significant and is notably smaller in size.

Table 8 reports a horse race between the scale effect (measured by a states average area in the two last periods) and caloric observability. We compare the times before and after the structural changes to the end of the Middle Ages, using our data points 1477 and 1789. Geographic area in earlier periods predicts state size in both estimations. However, in 1477 caloric observability determines state size significantly, and even has a larger effect than lagged area. In 1789, the lagged area shows a very high coefficient of around 0.9 while caloric observability is insignificant. These results confirm that state size at the end of the Middle Ages depends on caloric observability, but it explains modern state size only indirectly—via the state size achieved in earlier periods, presumably locked in by increasing returns to scale.

VI. Conclusion

This paper has studied the determinants of tax capacity in medieval Central Europe. Because the HRE was a federation of states for hundreds of years, we have been able to connect the
location, history and geographic circumstances of hundreds of states via our model. We have shown theoretically and empirically that the observability of agricultural output, via its impact on taxation capacity and the political structure of states, was a primary determinant of state size and survival in medieval Central Europe. We employed the theory of incomplete contracts to shed light on the dynamics of state capacity, before revolutionary social and economic events, from 1496 onwards, changed the game.

Our results provide evidence for the interaction of agriculture, climate, and geography in explaining political outcomes such as state capacity or regime. This adds a new perspective to the existing large and influential literature that links geography, climate and agriculture to long-run differences in economic outcomes (Diamond, 1999; Olsson and Hibbs, 2005). We have proposed a GIS measurement of observability of agricultural output that actually measures the degree of information asymmetry in an early society. As this index is well grounded in theoretical economic reasoning, it is potentially useful for other research endeavors in economic history, and long-run development.

This paper is a starting point for important further analyses—for example, why agricultural observability lost its explanatory power for state capacity during the early-modern period. This step would improve our understanding of the dynamics of state capacity in Europe over the last 1000 years. Potential factors to examine are the increased impact of technological innovations (e.g., De la Croix et al., 2017), or advances in education during the Reformation (Dittmar and Meisenzahl, 2017), which led to increased urbanization and reduced a state’s dependence on agricultural output for revenue. There are also opportunities for further study of the role of this observability mechanism in single states and other regions of the world.

DATA APPENDIX (FOR ONLINE PUBLICATION)

A.1. Dependent Variable

A.1.1. The Underlying Maps

The area of a state ("reichsunmittelbares Territorium") is calculated based on shapefiles created from maps of the non-Italian parts of the Holy Roman Empire printed in Wolff (1877). One of those maps, "Deutschland beim Tode Karl des IV. im Jahre 1378" ("Germany at the death of Charles IV. in the year 1378") is shown below in Figure A.1. Note that this map incorrectly includes the state of the Teutonic Order, so when digitizing the map we excluded this area. The maps are available here: http://gei-digital.gei.de/viewer/javax.faces.resource/pdf-icon32.png.xhtml?ln=images/ (accessed on January 22, 2016).

Figure A.1: Germany at the Death of Charles IV. in the Year 1378 (Wolff 1877)
A.1.2. States in the Holy Roman Empire 1250–1789

Figure A.2: The Holy Roman Empire and its territorial states (gray) and city states (red) at our sampling years
A.1.3. Historical Background of the Sampling Years

(i) 1250 was the year of the death of Frederick II., the last Emperor of the Staufer dynasty. The Staufer dynasty had ruled the Empire as kings and emperors for more than 110 years. The whole dynasty (and with them central power) collapsed soon after, in 1254, when his only son Konrad IV., who was King of Germany but never Emperor, died. Following the collapse of the Staufer dynasty, a 20 year period called the “Great Interregnum” began, in which there was no elected Emperor but four elected kings. The kings were not universally accepted by the powerful princes, and so did not rule the Empire. In this period, known as an age of insecurity, violence and anarchy, many of the numerous city state (free and imperial cities) emerged and political fragmentation increased further.

(ii) 1378 was the year Emperor Charles IV died. This year marks the peak of the political fragmentation of the Empire—a situation that was made permanent by the Golden Bull of 1356. Furthermore, while considered by some as one of the greatest and most influential medieval German Emperors, he failed to preserve the powerful position of his dynasty, the Luxembourgians, as he pledged away a lot of the territories under his control, in order to pay his large debts. This further weakened central authority and helped to increase the political fragmentation of the Empire.

(iii) 1477 was the year in which Charles the Bold, Duke of Burgundy died. With his death, the Duchy of Burgund, one of the largest states in Europe, which could be considered an independent, middle-sized power (although de jure part of the HRE), collapsed and was split after violent hostilities. Some parts of the Duchy fell to France and the remainder was integrated into the HRE as smaller political entities (like the Duchy of Brabant). Furthermore, through marriage, the Habsburgs gained control over the remaining parts of Burgundy and thus, the death of Charles the Bold was the decisive event in the ascent of the House of Habsburg to world power. A period with slowly declining political fragmentation began.

60 Political fragmentation in the 13th century was already much higher than during the 12th century. This was due to the fact that, as a consequence of the struggle between Henry the Lion, Duke of Saxony and Emperor Frederick I., the old and quite large stem duchies ("Stammschöffenländer") were dissolved and partitioned into smaller (and even further divisible) territories. This should have weakened the position of dukes and princes towards the Emperor and hence strengthen central power, but in the long-run, had the opposite effect.
(iv) 1556, the year after the peace of Augsburg settled the confessional division of Germany for the next decades and ended the first wave of religious wars in the Holy Roman Empire. However, it also was the year when Charles V, probably the most powerful European monarch after the fall of Rome, abdicated from the throne due to his setback against the protestant princes and his lack of loyal vassals within the Empire. His reign marked the peak and turning point of the power of the House of Habsburg as his resignation from the throne and its defeat by the princes of the Empire was the starting point of the slow decline of the Habsburg’s power.

(v) 1648, the year when the Thirty Years War ended, with the Peace Treaties of Westphalia. This led to notable territorial changes, as some large and powerful states like Brandenburg or Hesse integrated smaller territories into their states. Furthermore, several imperial cities disappeared, becoming part of France or of Switzerland (whose independence was officially acknowledged). Finally, it settled the confessional question within the Empire.

(vi) 1789, the year when the French Revolution began and triggered a series of events and wars, resulting in the demise of the HRE and the most significant reshaping of the landscape of states in Central Europe since the dissolution of the stem duchies in the 12th century.

A.1.4. De Facto vs. de Jure Independence of States in the Maps

City states are often among those territories for which it was not absolutely clear what degree of independence they had, regardless of their de jure status. It is well known that some cities had gained certain independence from their rulers, while never being officially considered as imperial cities. By the same measure, there were imperial cities that were never truly independent of their former ruler although they were granted “Reichsunmittelbarkeit” by the Emperor. We consulted standard sources on the history of German cities such as Köbler (1988) or Keyser and Stoob (1939–1974) and other studies on imperial cities, including Cantoni (2012) and followed their judgement about whether a city was de facto, and not just de jure, an imperial city. This is also an issue for several territories that were ruled by the Emperor or another high-ranked noble (like an elector) but where never part of their core territory. Two of these territories were the margraviates of Ober- and Niederlausitz (Upper and Lower Lusatia). Hence, some historians argue that the
power of those rulers over the territory was limited if non-existent. Therefore, we decided to treat the Lausitz territories as independent states.

### A.1.5. Coding Example of a Difficult Case

A difficult of a different case to code is the county of Sponheim which consisted at the beginning of the 14th century, of two separated territories, the “Vordere” and “Hintere” Grafschaft of Sponheim. When the dynasty ruling the “Vordere Grafschaft” (the front county) died out, one fifth of the County went to the Electoral Palatinate and four fifth to the Count controlling the “Hintere Grafschaft” (the back county). After 1437, the Margrave of Baden and the Count of Veldenz inherited both parts of the County. Both rulers decided not to split the County but to rule it together as a condominium. Another change occurred in 1559, when the Princedom of Pfalz-Simmern (who had inherited the part of the County of Veldenz) bought the Electoral Palatinate’s shares in the “Vordere Grafschaft”. Simultaneously, it decided to give away the half of the “Hintere Grafschaft” to the Duchy of Pfalz-Zweibrücken. This resulted in the following situation: the “Vordere Grafschaft” belonged three fifths to Pfalz-Simmern (since 1559 Electoral Palatinate) and two fiftha to Baden. The “Hintere Grafschaft” belonged half to Baden and half to Zweibrücken. Finally, in 1707, the Margraviate of Baden-Baden and Electoral Palatinate split up the “Vordere Grafschaft” and in 1776, the “Hintere Grafschaft” was split in half by the Margrave of Baden and the duke of Pfalz-Zweibrücken. After 1815 the territory was integrated into Prussia and disappeared. In 1477 and 1555, i.e. during the condominium, we decided to consider the whole territory as county of Sponheim. Wolff, in his 1556 map has assigned the four separate territories of the county to either Pfalz-Simmern or Baden-Baden, Pfalz-Zweibrücken and the Electoral Palatinate. One cannot be sure whether he has assigned it to Pfalz-Simmern or Baden-Baden as both have the same color. In addition, this does not reflect the actual situation in 1556 (according to our sources), rather this is the situation in 1559 (when one assumes that he has assigned the “Vordere Grafschaft” to Baden and not to Pfalz-Simmern). For 1648 and 1789 we follow Wolff, who no longer included the county of Sponheim but assigned its territory to Pfalz-Zweibrücken, Electoral Palatinate and Baden-Baden (or Baden, respectively).
A.2. Control Variables

The spatial datasets were each converted into WGS 1984 UTM 32N projection. State type and “State in 1150” dummies are calculated from the shapefiles of Wolff’s maps (1877). This is also the case for the variable “Outer Boundary” reporting the share of a states’ border that is an outer boundary of the HRE.

Area Types. We have computed the (natural logarithm of the) area within each state that consisted of forests, swamps and floodplains (in m$^2$) in the pre-modern period and hence was very likely not settled or used for agricultural purposes. Floodplains and swamps might also have played a role as source of germs and diseases. Data is taken from a map by Schlüter (1952) that we have digitized. His map only covers the area of contemporary Germany.

Average Terrain Ruggedness. Following Riley et al. (1999) average ruggedness of a states’ territory is calculated as the negative value of the derivative of the ruggedness index of a digital elevation model. The calculations are based on the elevation raster of Nunn and Puga (2012) (see above). Terrain ruggedness was calculated using QGIS.

Average Temperature. Historical average temperature for a state is taken from the data set of Guiot and Corona (2010). They constructed a grid cell database of historical European temperatures and their deviations from the average temperature in 1960–1990. We use this data set to calculate, for each state, the average temperature deviation in the period from 800 to 1378. To calculate the average temperature deviations for each grid we follow the interpolation procedure of Anderson et al. (2016) by filling in missing values with the inverse distance weighted average temperature of the twenty-four nearest neighbor grid points.

Battles. Number of battles per km$^2$ that have taken place in a state in the period between two of our maps (e.g. between 800 and 1250 between 1250 and 1378, between 1378 and 1477 etc.). Information of the date and location of the battles is taken from Bradbury (2004), Clodfelter (1992) and Darby and Fullard (1978).

Distance to City State. Distance to city states is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. In a second step, the Euclidean distance
from each of the 1,000 points per state to the closest Imperial city was calculated. In a last step, these distances were aggregated by state. The location of city states follows the maps of Wolff (1877) but we have corrected/ supplemented them—if necessary—with information from Köbler (1988), Keyser and Stoob (1939–1974) and Jacob (2010).

**Distance to Major Rivers.** Distance to major rivers is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. In a second step, the Euclidean distance from each of the 1,000 points per state to the to the closest major river (see Figure A.5) was calculated. In a last step, these distances were aggregated by state. For the location of the rivers, we used the dataset for 'WISE large rivers' shapefile, which can be downloaded here: [http://www.eea.europa.eu/data-and-maps/data/wise-large-rivers-and-large-lakes](http://www.eea.europa.eu/data-and-maps/data/wise-large-rivers-and-large-lakes) (last accessed May, 30th 2016).

**Distance to Natural Resources.** We have calculated seven variables reporting the distance to natural resources (copper, gold, iron, lead, potassium salt, rock salt and silver). Distance to natural resources is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. In a second step, the Euclidean distance from each of the 1,000 points per state to the closest deposit of the respective natural resource was calculated. In a last step, these distances were aggregated by state. The location of natural resource deposits is taken from Frenzel (1938) and Elsner (2009).

**Distance to Roman Roads.** Distance to (minor and major) Roman roads is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. In a second step, the Euclidean distance from each of the 1,000 points per state to the to the closest Roman road was calculated. These distances were aggregated by state. Locations of Roman roads (minor and major) originate from a shapefile included in the “Digital Atlas of Roman and Medieval Civilizations” [McCormick et al. 2013]. The shapefile is based on the map of Roman roads in the Barrington Atlas of the Greek and Roman World (Talbert 2000). It can be downloaded here: [http://darmc.harvard.edu/icb/icb.do?keyword=k40248&pageid=icb.page601659](http://darmc.harvard.edu/icb/icb.do?keyword=k40248&pageid=icb.page601659) (last accessed September, 24th 2015).
Distance to Medieval Trade Road. Distance to medieval trade routes is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. The Euclidean distance from each of the 1,000 points per state to the to the closest medieval trade route was calculated. In a last step, these distances were aggregated by state. Location of trade routes are obtained by digitizing a map on “Medieval Commerce” from Shepherd (1923). The map can be downloaded as pdf from here: https://www.lib.utexas.edu/maps/historical/shepherd/europe_mediaeval_commerce.jpg (last accessed July, 10th 2017).

Distance to Trade Fairs. Distance to trade fair is calculated as follows: Points with random location were generated until 1,000 points fell in into each state. The Euclidean distance from each of the 1,000 points per state to the to the closest trade fair city was calculated. These distances were aggregated by state. The locations of the fairs were taken from Ditchburn and Mackay (2002).

Maximum Elevation. Maximum elevation of each state in meters. Data is based on the Digital Elevation Model (DEM) of the U.S. Geological Survey’s Center for Earth Resources Observation and Science (EROS), namely the GTOPO30 dataset, which can be downloaded here https://lta.cr.usgs.gov/GTOPO30 (last accessed May, 30th 2016). The GTOPO30 has a spatial resolution of 30 arc seconds.

Plough Suitability. Plough suitability of a states’ soils are measured by the share of its area which has luvisol soils. Data on location of luvisol soils is taken from the European Soil Database version 2 provided by the European Soil Data Center (ESDAC). We used the 1km*1km raster data set downloadable here (upon request): http://esdac.jrc.ec.europa.eu/content/european-soil-database-v2-raster-library-1kmx1km (last accessed June, 20th 2017).

Pre-Historic Settlement Area. We have computed the (natural logarithm of the) area within each state that was already settled in pre-historic times (in m$^2$). This information stems from Schlüter (1952).

Latitude. Minimum longitudinal coordinates a states’ centroid (mid-point) in meters. Calculated
using QGIS.

**Longitude.** Minimum longitudinal coordinates of a states’ centroid (mid-point) in meters. Calculated using QGIS.

**Relative Cereals Suitability.** An index of caloric suitability of cereals relative to roots and tubers for each state was generated according to the logic of Mayshar et al. (2015) using data from Galor and Özak (2015). This index measures the difference between the maximum yield from plants that are appropriable, and the maximum yield from roots and tubers. Appropriable plants (“cereals”) included alfalfa, banana, barley, buckwheat, cabbage, canary grass, chickpea, citrus, coconut, cow pea, dry pea, flax, foxtail millet, greengram, indigo rice, jatropha, miscanthus, oat, oil palm, olive, pasture grass, pasture legumes, pearl millet, pigeon pea, pulses, rape, rye, sorghum (subtropical), sorghum (tropical highland), sorghum (tropical lowland), soybean, spring barley, spring wheat, sugar cane, tea, wetland rice, wheat, winter barley, winter rye, and winter wheat. Roots and tubers were carrot, groundnut, onion, yams, and white yam.

xiv
Note: The instrument from Alesina et al. (2013) shows only minor variation within our sample. We employ the idea by Andersen et al. (2016) based on data from Panagos (2006) and Van Liedekerke et al. (2006).

Figure A.9: Usage of the Heavy Plough [Alesina et al. 2013; Andersen et al. 2016]

Note: Information of the date and location of the battles is taken from Bradbury 2004, Clodfelter 1992 and Darby and Fullard 1978.
